ABSTRACT
Today’s technology offers a wide variety of sensors. Although many sensing applications have been produced, there is no support for the design of applications offering physical interaction. In order to make a step towards such a design framework this paper analyzes different means of sensing of humans and human activity. In particular we identify six sensing goals, referred to dimensions of sensing: ID (1), Object Use (2), Location (3), Bio Signs/Emotions (4), Activity (5) and Interaction among humans (6). Those dimensions together with different sensor placements are used to review and analyze ubiquitous computing research related to physical interaction and sensing. The final discussion draws conclusions from this analysis with respect to appropriateness of sensors and sensor placement for different sensing dimensions.

1. INTRODUCTION
Mobile devices give access to computing services without the constraint of sitting in front of a desktop computer. This poses new challenges for human-computer interaction: mobile users can be busy with real-world activities at any time while using mobile devices, such as crossing a busy street, discussing in a meeting or riding a bicycle. Previous work [15, 29, 24, 13] proposes physical interaction, e.g. tilting a device for configuring a device’s functionality, as new and convenient forms of interaction for mobile user scenarios. The notion of implicit interaction takes this a step further and suggests to sense “an action, performed by the user that is not primarily aimed to interact with a computerized system but which such a system understands as input.” [28]. That means, the user interacts with physical objects in a natural way, but a computer system also can extract inputs from these actions for the use in meaningful applications. System inputs generated from interaction with physical objects already have been used for coupling physical objects with computer applications as tangible user interfaces [18], computer-assisted furniture assembly [1], future restaurant scenarios [17], tracking a patient’s medicine cabinet [31] or work-flow monitoring in a chemical lab [3]. Empowering a computer system to process physical user inputs requires augmentation of today’s computer nerve-endings, such as mouse and keyboard, by sensors: perception and interpretation of real world phenomena enables a computer system to participate in the user’s physical environment and serve the user in an appropriate way. Today’s technology offers an astounding variety of sensors more or less suited for different applications: accelerometer, oximeter, microphone, gyroscope, temperature, skin resistance, etc. However, this variety of sensors makes it difficult for an application designer to choose the most appropriate subset which depends on the application. Although quite a variety of applications have been produced, there is no support for the design of applications offering physical interaction, such as toolkits or style-guides available for GUI development.

This paper is a first step to develop a conceptual framework, that allows to categorize existing sensors and evaluates their utility in various applications. Eventually, this framework shall guide application designers to choose meaningful sensor subsets, inspire new systems and evaluate existing ubicomp applications.

Section 2 briefly summarizes related work, section 3 describes a conceptual categorization framework of sensors and reviews existing ubicomp applications by means of the framework. Section 4 presents an evaluation of sensing technology in respect to the framework. Section 5 concludes the paper.

2. RELATED WORK
Related research attempts have been made to develop frameworks and infrastructure for reusable sensing mechanisms. The context toolkit [26] supports the development of context-aware applications with useful abstractions from the actual sensors. However, it mostly deals with the context recognition on an abstract level decoupled from the variety of sensor technology. Furthermore, it limits applications to single sensor usage as only one context abstraction can be mapped to one physical sensor. In contrast to that, the TEA architecture [32] focuses on low-level abstractions for simple sensors, which depends to much on the used sensors and, as such, does not provide reusable perception mechanisms either. The sensor classification scheme [37] facilitates the comparison and classification of sensors.

This paper was presented at "Physical Interaction (PI03) Workshop on Real World User Interfaces", a workshop at the Mobile HCI Conference 2003 in Udine (Italy). September 8, 2003. 3. FINDING THE APPROPRIATE SENSORS

Advances in sensor technology such as form-factor, power consumption, processing requirements and cost-effective fabrication offer a wide variety of integration into devices and appliances. An application that enables implicit interaction uses sensors as nerve-endings to perceive the environment. But what are the appropriate sensors? Instead of an technology-oriented view we take the perspectives of a designer and an engineer: sensing goals, referred to as dimensions of sensing, and actual placement of sensors.

3.1 Logical View: Dimensions of Sensing

Typically, application designers are more interested in the opportunities sensors can offer, than in the actual technology itself. As physical interaction shall happen between human and machine, all characteristics that describe the user’s situation are of interest to the application. For that, in the last years a very general definition has been established [9]: ”Context is any information […] to characterize the situation of an entity”. Unfortunately this definition is too general and does not really help for application design. Thus, we identify six sensing goals, referred to as dimensions of sensing, that give a more precise description of user context.

The first dimension is a user’s ID - this has been widely used already, e.g. for customizing and personalizing services without requiring explicit user inputs [25, 4]. In fact, we use a more general definition of ID ranging from differentiating people to actual identification. The second dimension is Location; it has been the dominant implicit input used in ubiquitous computing applications [35, 8]. It does include 3D coordinates but also semantic location descriptions. The third dimension, Activity, describes the task the user is performing which ranges from simple moving patterns [33] to precise job descriptions. The fourth dimension, Object Use, comprises collocation of a user to an object [25], carrying an object [20] and the actual use [1]. The fifth dimension, Bio Signs/Emotions, describes the internal state of the user. Research in this area is still in its infancy. First results could be obtained with heart-rate and skin-resistance, for reasoning about a user’s affects [23]. The sixth dimension, Human Interaction, characterizes the relationship between humans including simple collocation, listening to a speaker, gaze, and actual interaction as discussion. In section 3.3 we will use these six dimensions of sensing together with choices of sensor placement to categorize current sensing technology.

3.2 Physical View: Placement of Sensors

An application engineer has to consider the possibilities of sensor placement in the physical world: e.g. a traffic jam can be remotely detected by a camera or locally at each car through mutually exchanged distance and speed information. Both choices are appropriate for the intended purpose but have different side-effects: the camera has to be mounted once and works for all cars, but only at one location. As a side-effect its use could be extended to other applications, e.g. criminal search. The local set-up instead requires individual effort at each car but users have the choice to participate in the system or not and it works everywhere.

We identify four different categories of sensor placement. In Environment refers to stationary installed sensors, e.g. in the floor, walls, where placement can only be changed with effort. Whereas In Environment installations work with all users at the stationary location on Human has the opposite characteristics: only users wearing the sensors can participate, but therefore they are not bound to a location. On Object is in between the two previous categories, as objects can be personal and can be carried with a human (e.g. key), but also stay at a certain location (e.g. chair). This distinction depends on the object. Additionally, mutual collaboration defines sensing system that always require more than one unit in order to operate properly, e.g. triangulation of signal strength for localization.

3.3 Review: Sensors in Ubicomp Research

Based on own experience with sensors and literature review we compiled a table (Fig. 1) characterizing sensor technology in respect to the six sensing dimensions and the four sensor placement possibilities. This table should be used as reference for application developers during the process of finding the appropriate sensor for their application.

In each table cell sensors are aligned due to bandwidth consumption and quality of perception in respect to the dimension. The alignment due to precision and bandwidth should be seen as rough estimation for relative comparison between sensors occurring in the same table field. For recognizing a person’s ID the table shows four choices of sensors for installation in environment in the upper left cell. Obviously, the best results can be achieved with biometric sensors [36], such as finger print or iris scan, as represented by vertical alignment in the cell. Methods based on vision [10], audio or load-cells embedded into the floor [6] deliver less quality. Horizontal alignment in the cell shows, that data generated by load-cells and finger print sensors consumes lower bandwidth than methods based on vision or audio. Inertial sensors placed on object and on human can be used to sense typical movements, e.g. perceiving the signature at a pen, for identification. [27] reports about using vision; [19] about using audio worn on human for people identification. Location systems [16] can also be used for identifying people at different locations. As these systems require both sensors worn by human and installed base stations those system appear in the mutual collaboration column. For detecting object use load-cells [30] have been proven useful installed both in environment and on object. Object classification with vision is well established in static settings, occlusion during dynamic use can be challenging. Audio is another option, if the object use generates characteristic sounds. The use of inertial force sensors placed on object has been successfully used [15, 29, 24, 13] for object use. Obviously, motion during object use can be also sensed on human but with less quality. Audio on human is also possible [21] but is an indirect measurement compared to on object placement. Location systems can give hints as well for object use, e.g. teleporting X Windows to user’s current location [25]. Location is the most explored sensing dimension in ubiquitous computing. Load-cells [30], vision [5] and audio [7] have been explored in different project. Coarse location can be also gained through passive-infra-red sensors, mechanical switches or IR-barriers.

Table 2: Evaluation

Looking placements more globally, table 2 depicts that in environment and on human offer the best sensing results. Analyzing the dominant factors for each placement, it points out that video and audio are most prominent for in environment sensing. However, the perception quality depends

---

1Actually GPS is a mutual technology requiring a receiver in collaboration with satellites in space. However, as satellites are so ubiquitous and invisible anyway we consider them as a "natural" resource and view the receivers only.

On object and on human the primary outdoors is GPS\(^1\), more low-level information deliver humidity, inertial or pressure sensors. The variety of location systems based on mutual collaboration is huge: differential GPS, ultra-sound, radio etc. Sensing bio signs/emotions with in environment sensor-settings is difficult: [10] and [12] report vision and audio for reasoning on user's bio signs/emotions. Augmented objects measuring force and touch [2] can give some hints about bio signs/emotions. However, most promising are on human measurements such as [14, 22]. Activity can be well sensed with special purpose system, such as commercially available smart white boards. Load-cells, passive infra-red, pressure and capacity sensors can be used for low-level detection only. On human sensing has been well explored for motion activity [11]. Location system can give hints reasoned from semantical location descriptions. Interaction among humans has not been explored very well. In environment sensing systems based on vision, load-cells and audio could help to perceive characteristics of interaction, such as collocation, gestures or speech. The on object field is blank as objects are not involved here. On human the same sensors can be used as for activity if measurements are correlated among interactors. Location system do not really help here, as collocation is not significant for interaction.

4. DISCUSSION

As a result of the review presented in the previous section, this section discusses the appropriateness of different sensor placement for the six sensing dimensions. Table 2 evaluates our classification of sensing technologies due to the dimensions of sensing and sensor placement. In particular we differentiate between not applicable, if a combination does not make sense, possible for instances with very low quality of perception, and good and very good for more promising solutions.

It points out, that in environment placement is the primary choice for ID sensing. As our focus is on human sensing it is not surprising that on object is well suited for object use. On human is suited for direct measurements of human-centric sensing aspects, such as bio signs/emotions and activity. Mutual collaboration sensors, such as the location systems perform best location sensing, but also can give hints for other dimension. Quite interestingly, each sensor placement is meaningful for at least one sensing dimension.
on computational expensive recognition, as video and audio per se can only provide indirect measurements which are less power than e.g. direct activity with inertial sensors. Nevertheless, once an environment has been augmented with sensors, e.g. Smart Rooms, applications work without additional instrumentation of users or objects. It also can give hints for human-human interaction from an outer view.

As physical interaction with everyday object mostly involves movements, such as grasping, moving or turning, the dominant sensor technology for object use are inertial sensors. On human placement is suited for various sensors such as inertial sensors, audio, bio sensors and also video to a certain extend. In regards of human sensing on human also represents the closest to phenomena placement. Due to the high relevance of location in the real world mutual collaboration sensors can provide coarse information about object use, activity and in environment. This also explains why in the first years of context-aware computing mostly location was regarded as context. It can do a lot but in direct comparison with on object and on human sensing location system are in an inferior position.

5. CONCLUSION
This paper is a first step to systematize the use of sensor technology. Therefore, six dimension of sensing have been identified representing the sensing goals for physical interaction. We reviewed existing ubiquitous computing research for an evaluation of sensing technology with respect to the dimensions of sensing and physical sensor placement opportunities. This enables to support application designers finding appropriate sensors during system design.
